Liquid phase H₂O and D₂O were measured with mid-IR lasers with wavelengths of 2.9 μ m and 3.9 μ m. The laser power change over time was observed when the water isotope specie was continuously replaced. Additionally, the concentration ratio of H₂O and D₂O as a function of time was obtained. These results indicate that quantitative measurement of water isotopes using mid-IR lasers in real-time has been successful.

The geoscience and nuclear fusion fields have investigated the transfer/diffusion of water isotopes such as H₂O, HDO, and HTO [1, 2]. Thus, a real-time measurement method was required to discuss this phenomenon quantitatively and constantly monitor it. Mid-IR laser absorption spectroscopy is an effective method to realize the real-time measurement of water isotopes. H₂O, HDO, and HTO have a strong absorption peak in wavelengths of 3.0 μ m, 4.0 μ m, and 4.4 μ m, which is attributed to the hydroxyl group stretching mode [3, 4]. Therefore, a high-sensitivity absorption measurement of water isotopes can be realized by using a mid-IR light source. Also, laser absorption measurement has the advantage of high time resolution and high sensitivity than measurement by lamp-source due to the laser with higher monochromaticity and brightness. Therefore, we tried to develop a real-time measurement system for water isotopes using mid-IR lasers. In this research, as the first step, we demonstrated the proof-of-principle of liquid-phase H₂O and D₂O measurement using mid-IR lasers.

Figure 1 shows a liquid phase H₂O and D₂O detection system using a mid-IR laser for measuring the time trend of detected laser power passed through a sample cell when changing water isotope species. This system was mainly constructed with lasers, a dichroic mirror (DM) with high transmittance in 3.0 μ m and high reflectance in 4.0 μ m, a sample cell, a band-pass filter with high transmittance in 4.0 μ m, and a power meter. In this system an Er:YAP continuous-wave (CW) laser with a wavelength of 2.9 μ m [5] and Quantum a Cascade Laser: QCL (Thorlabs, QF4050C2) with a wavelength of 3.9 μ m were used as a beam probe. These lasers entered a sample cell at the same time and an optical path. The sample cell was constructed

with two sapphire plates of 10 × 10 × 0.3t mm, and the cell length was around 1 μ m. The diameter of these incident beams was 5 mm at the cell. After the laser beams passed through the cell, 2.9 μ m and 3.9 μ m lasers were measured with power meter1 (Thorlabs, S350C) and power meter2 (Thorlabs, S314C) which have a power resolution of 1 mW and response time of 1 s. In this experiment, purified water (H₂O) and heavy water (D₂O) with a concentration of 99.95% (Merck, 1.13366.0009) were used as a sample. Here the D₂O was used as a test sample instead of HDO to observe absorption in 4.0 μ m caused by the OD-stretching mode. While the sample cell was irradiated with lasers, the water isotope species of the inside cell was replaced by a capillary force. The sample cell was fixed in space using a clip-stand. The H₂O or D₂O was placed under the cell and attached to the bottom of the cell by a lifting device. After attaching the water to the bottom of the cell, it gradually soaked into the cell by capillary force.

Figure 2 (a) is the detected laser power in a wavelength of 2.9 μ m and 3.9 μ m as a function of time while changing water isotope species. The time regions of #1, #2, and #3 in Fig. 2 (a) mean that the component inside the cell was replaced air with H₂O, H₂O with D₂O, and D₂O with H₂O, respectively. At 24 s, 351 s, and 772 s, each sample was

attached to the bottom of the cell. From 0 s to 24 s when did not exist water in the cell, averaged laser powers ($I_{in,3}$ and $I_{in,4}$) in 2.9 μm and 3.9 μm were calculated. The values were used as a reference for incident laser power in this experiment. The $I_{in,3}$ and $I_{in,4}$, which were removed Fresnel loss from raw data, were 152.5 mW and 36.8 mW. The rapid increase of 3.9 μm laser power around 40 s was attributed to decreasing reflection loss because the refractive index difference was decreased when the air in the cell was changed to water. In #1, laser power in 2.9 μm dramatically decreased by around 35.5 mW and laser power in 3.9 μm keep a constant value of 32.7 mW. Comparing $I_{in,3}$ to averaged 2.9 μm laser power from 132 s to 164 s, the transmittance of H₂O was 30.9%. This result indicates that the cell was full of H₂O and the 2.9 μm laser was strongly absorbed by it. In #2, laser power in 3.9 μm decreased by 16.1 mW, and that in 2.9 μm increased to around 100 mW. This result suggests that the amount in the cell replaced H₂O with D₂O and the absorption in 3.9 μm by D₂O became dominant. In #3, the laser power in 2.9 μm decreased by 35.5 mW, and that in 3.9 μm increased by 32.3 mW due to the replacement of D₂O with H₂O in the sample cell.

The concentration ratio of D₂O and H₂O ($R = C_{D2O}/C_{H2O}$) was derived from the absorbance in 2.9 μm and 3.9 μm defined by detected laser power ($I_{out,3}$ and $I_{out,4}$) and incident laser power. The absorbance A_3 in 2.9 μm or A_4 in 3.9 μm was expressed $A_i = \log_{10}(I_{in,i}/I_{out,i}) = k_i L$, where $k_i = \epsilon_{H2O,i} C_{H2O} + \epsilon_{D2O,i} C_{D2O}$ ($i = 3, 4$). The $\epsilon_{H2O,3}/\epsilon_{H2O,4}$ and $\epsilon_{D2O,3}/\epsilon_{D2O,4}$ were the molar ex-

	$\epsilon_{H2O,3}$	$\epsilon_{D2O,3}$	$\epsilon_{H2O,4}$	$\epsilon_{D2O,4}$
[L/(mol·cm)]	152.5	43.6	45.4	123.0

inction coefficient of H₂O in 3.0 μm /4.0 μm and D₂O in 3.0 μm /4.0 μm region, and these were summarized in Table 1. L was a sample length. The $\epsilon_{H2O,3\mu\text{m}}$ and $\epsilon_{H2O,4\mu\text{m}}$ were estimated from an absorption coefficient (α) in 2.9 μm or 3.9 μm of H₂O [6] and the Lambert-Beer Law of $I_{out} = I_{in} 10^{(-\epsilon CL)} = I_{in} \exp(-\alpha L)$. Finally, the concentration ratio $R(t)$ was expressed by transforming the ratio of absorbance (A_3/A_4) as shown in (1).

$$\frac{C_{D2O}}{C_{H2O}} = \frac{A_3 \epsilon_{H2O,4} - A_4 \epsilon_{D2O,3}}{A_4 \epsilon_{D2O,3} - A_3 \epsilon_{D2O,4}} = R(t). \quad (1)$$

Figure 2 (b) shows $R(t)$ from 350 s to 550 s while replacing H₂O with D₂O. Around 351 s, the R was almost zero. This result suggests that the D₂O was not in the cell in the time region. Around 420 s, an increase in $R(t)$ was observed because the D₂O gradually soaked into the cell. Finally, the $R(t)$ was increased until around 500 s, and the value was saturated at around 5.0 in 550 s. This result indicates that the replacement of H₂O with D₂O reached an equilibrium. Although D₂O was completely replaced with H₂O after 1000 s in #3, in #2, H₂O existed in the sample cell because part of D₂O in the cell was replaced by H₂O in the atmosphere. From these results, we have succeeded in quantitative observation of the dynamics of an H₂O and D₂O transfer phenomenon using mid-IR lasers.

In summary, H₂O and D₂O in a liquid phase were measured with 2.9 μm and 3.9 μm lasers when a component of water isotope species inside a cell was continuously changed. Also, a concentration ratio as a function of time was obtained from laser measurement. Thus, we succeeded in quantitative measurement of a water isotope using a mid-IR laser in real-time.
