A study of ionization location of neutral particles in LHD

The plasma boundary in terms of the neutral ionization is investigated for a detached plasma sustained by ECH (electron cyclotron heating). Since intense line radiation implies occurring vigorous atomic processes, the radial ionization location of neutrals can be approximated by the dominant line radiation location. We first determine the electron temperature $T_e$ and density $n_e$ at such a location from a line intensity distribution of neutral helium, and then compare those parameters with the $T_e$ and $n_e$ profiles measured by the Thomson scattering. The dominant line radiation location can be thus located.

The temporal development of the discharge used for this study is shown in Fig. 1. Helium is used as the working gas and the gas-puff rate is feed-back controlled to follow the preset waveform of the line-integrated $n_e$ measured by the interferometer. As the central $n_e$, $n_e0$, is increased, the central $T_e$, $T_e0$, is lowered.

The divertor detachment is observed at around $t = 5$ s and terminated by the ICH (ion cyclotron heating) input at $t = 6$ s which is judged by the ion saturation current measured by the electrostatic probes on the divertor plates. It is observed that $n_e0$ is stepwise increased during the detachment, and is gradually decreased after the re-attachment. Our interest is whether the ionization location of neutral atoms is displaced during the period of the divertor detachment. If the plasma shrinks as a result of the detachment, the ionization location could be inward shifted accordingly.

Nine emission lines of neutral helium are used to determine $T_e$ and $n_e$ [1]. Figure 1 (c) shows the temporal variations of $T_e$ and $n_e$ determined from helium lines. The both results respectively show similar temporal variations to their central values in Fig. 1 (b). This result indicates that the dominant ionization location is determined by neither local $T_e$ nor $n_e$. It is noted that the agreement between the locations independently determined by $T_e$ and $n_e$ is satisfactory, which supports the reliability of the present diagnostic methodology.

A remarkable characteristic is that the dominant ionization location is virtually fixed as seen in Fig. 1 (d) while the $T_e$ and $n_e$ values change in the course of time. It is also noticed that no displacement of the emission location is seen in the period of the divertor detachment. These results suggest that the dominant ionization location is determined by the magnetic field structure and is irrespective of the plasma conditions.
